Atmospheric oxidation of monoterpenes (C$_{10}$H$_{16}$) contributes to ambient particle number and mass concentrations due, in part, to the resulting peroxy radicals undergoing auto-oxidation to low-volatility highly oxygenated molecules (HOMs). Only one of the structural isomers of the first-generation hydroxy peroxy radical (C$_{15}$H$_{15}$O$_2$), that formed with an opening of the cyclobutyl ring, is thought to be responsible for the majority of HOMs derived from OH-initiated oxidation of $\alpha$- and $\beta$-pinene. We constrain the yield and auto-oxidation rate of this isomer by using a unique combination of isotopically labeled precursors, such as D$_3$-$\alpha$-pinene, and direct measurements of peroxy radicals and closed-shell products after a reaction time of only $\sim$0.7 s. Using competitive rate studies and quantum chemical calculations, we find that the yields of these ring-opened peroxy radicals are 0.47 (0.2, 0.6) for $\alpha$-pinene and 0.66 (0.4, 0.8) for $\beta$-pinene, and the rates of auto-oxidation are 2.9 (1.1, 4.7) s$^{-1}$ and 0.8 (0.4, 1.6) s$^{-1}$, respectively, where values in the parentheses represent upper and lower bounds based on experimental and mechanistic uncertainties. These rates and yields are in general agreement with HOM yields determined from independent methods and in a range where OH driven monoterpene HOM formation will be atmospherically important for a wide set of conditions.

Environmental significance

Auto-oxidation of monoterpene (MT) derived organic peroxy radicals leading to HOMs is a key process for prompt formation of SOA observed in the troposphere and in atmospheric simulation chamber experiments. MT SOA is a significant contributor to fine particulate mass concentrations, affecting climate and human health. OH-oxidation of $\alpha$ and $\beta$-pinene is a major fate for MT. The fraction of the associated peroxy radicals which undergo auto-oxidation, and the rates of the auto-oxidation compared to bimolecular reactions are key metrics towards quantitative mechanistic predictions of SOA mass yields. We present experimental results for these two metrics, for which there is large variance in literature, that will allow for better descriptions of spatial and temporal variations in MT SOA production.

1 Introduction

Global emissions of biogenic volatile organic compounds (BVOCs) approach nearly a petagram of carbon per year (Pg C year$^{-1}$).$^{1-3}$ Subsequent atmospheric oxidation, initiated by reactions with ozone (O$_3$), hydroxy radicals (OH), or nitrate radicals (NO$_3$), leads to products of varying volatility that can affect the burden and composition of organic aerosol (OA), which in many regions of the world is the dominant component of atmospheric fine particulate matter (PM$_{2.5}$).** OA formation and growth on the timescales observed in forested environments and in laboratory chamber experiments indicate that organic peroxy radical (RO$_2$) auto-oxidation involving intramolecular RO$_2$ radical propagation with one or more O$_2$ additions is a key mechanism leading to the prompt formation of highly oxygenated molecules (HOMs), which have low to extremely low volatility.$^7$

Monoterpene oxidation is a major contributor to SOA in forested regions even where isoprene emissions far exceed those of monoterpenes, such as over the Southeast United States,$^{8-10}$ as well as in urban areas given that monoterpenes account for a large fraction of anthropogenic volatile chemical products.$^{11,12}$ Loss pathways of $\alpha$-pinene (AP) due to reactions with OH and O$_3$ are comparable, whereas OH oxidation is about an order magnitude faster than ozonolysis for $\beta$-pinene (BP) under typical conditions of the daytime when BVOC emissions are highest. Theoretical and experimental work have indicated...
HOM formation only from the first-generation RO₂ which have undergone opening of the cyclobutyl (or C-4) ring after OH addition to the less substituted (tertiary for AP and primary for BP) C of the C=σ double bond.¹⁴⁻¹⁶ Retention of the C-4 ring of the first-generation RO₂ prohibits intramolecular H-shifts by steric hindrance of the ring itself and due to the absence of a C=σ double bond (present only in the C-4 ring-opened isomer) that facilitates the intramolecular H-shifts.¹⁵

We report on experimental determinations of the yields of the C-4 ring-opened RO₂ from OH reactions with AP and BP, as well as the rates of auto-oxidation of the resulting first (C₁₀H₁₇O₃) and second generation (C₁₀H₁₇O₅) peroxy radicals by employing a chemical box model to constrain observations made using a fast flow tube coupled to a long time of flight mass spectrometer (L-ToF) employing ammonium-adduct (NH₄⁺) ionization to directly measure the suite of peroxy radicals and explain SOA mass yields, which are used in atmospheric chemical transport and climate models to describe OA formation.¹⁹

2 Methods

Experiments were conducted in a room temperature (21 ± 2 °C), atmospheric pressure (1016 ± 15 mbar) flow reactor with a 2.54 cm outer diameter. The entire 8.2 standard liters per minute (slpm) output from the flow reactor passes through a custom-built transverse ion–molecule reaction region (IMR) maintained at atmospheric pressure, and coupled to a Tofwerk AG long time of flight mass spectrometer (L-ToF-MS). The IMR, refined from that used by Zhao et al.²⁸ has an inner diameter matching that of the flow reactor to maintain laminar flow and constant flow velocity. A schematic of the transverse IMR is shown in Fig. S1.† NH₄⁺ reagent ions are generated by flowing 1.8 slpm UHP N₂ over the headspace of an ammonium hydroxide (NH₄OH) solution and through an inline²¹⁰Po (NRD) ionizer. The exit of the²¹⁰Po source is axially aligned with the entrance capillary of the LToF-MS and orthogonal to the reactor flow direction. Ions enter the sample flow from the outer wall and traverse the 2.2 cm across the sample flow to the LToF-MS capillary aided by a ∼1.5 kv cm⁻¹ electric field applied between the²¹⁰Po source and the capillary. Reaction products are detected as NH₄⁺ adducts.²¹,²²

Hydroxyl (OH) and hydroperoxyl (HO₂) radicals were generated by flowing 1 slpm of humidified UHP N₂ through a quartz housing containing a 185 nm radiation Hg lamp (PenRay). Water vapor (H₂O) is photolyzed to generate HO• from isopropanol added to the flow reactor. OH reagent ions are generated by mixing ratios of OH in the absence of NO, and up to 610 ppt at maximum NO (127 ppb, Fig. S3†). Energy barriers for the alkoxy isomerization reactions were calculated using a similar approach to the one detailed in Möller et al.²⁸ Briefly, the Spartan ‘18 program²⁷ was used to perform a systematic conformer sampling of the reactants and transition states using the Merck Molecular Force Field (MMFF) method with a neutral charge enforced on the radical atom. Initial geometry optimizations were carried out at the B3LYP/6-31+G(d) level of theory, and conformers within 2 kcal mol⁻¹ in relative electronic energies were optimized and their frequencies calculated at the oB97X-D/aug-cc-pVTZ level.²⁸⁻³⁰ The Gaussian 16 program was used to carry out these optimizations and frequency calculations. On the lowest electronic energy reactant and transition state conformers at the oB97X-D/aug-cc-

pVTZ level, single-point calculations were done at the ROCCSD(T)-F12a/VDZ-F12 level using the Molpro 2019.2 program. The stability of the wavefunction was checked at the CCSD(T) stage by running HF calculations (cc-pVDZ basis set using ORsCA 4.2.1 program) with 15 HOMOs and 15 LUMOs switched 10 times randomly and generating 100 input files with the orbital rotations applied. This indicated that no lowering of the wavefunction relative to the default solution was neglected for any of the reactants and transition states. For the products of the alkoxy isomerization reactions, only aug-cc-pVTZ optimizations were performed without a systematic conformer sampling step. This is because while the subsequent RRKM simulations are sensitive to the reactant and transition state energies, they are not sensitive to that of the products. However, products nevertheless need to be defined to run the simulations.

The master equation solver for multi-energy well reactions (MESMER⁴⁹) program was used to carry out the RRKM simulations to determine the fate of alkoxy radicals. The isomerization reactions were treated using the SimpleRRKM method with Eckart tunneling. The reactant alkoxy radicals were assigned as “modelled” in the simulations and given Lennard-Jones potentials sigma = 6.5 Å and epsilon = 600 K, and a $\Delta E_{\text{down}}$ value of 225 cm$^{-1}$, which are identical to those used previously for similar systems.⁵⁵,⁵⁶ The resulting quantum chemical output files are available here (https://zenodo.org/record/7214075#.Y3QrjexMJqs).

### 3 Results and discussion

A suite of products are detected from the OH-initiated oxidation of AP or BP in the presence of NO. Under low NO conditions and after ~0.7 s of reaction time between OH and the monoterpene, we detect a series of products containing 10 C and 16, 17, or 18 H atoms, one or no N atoms, with odd and even numbers of O (Fig. 1). The products with odd numbers of H and O atoms, particularly C$_{10}$H$_{17}$O$_x$ where $x = 3,5,7$ dominate the reaction mixture spectrum at short reaction time and low NO. Additionally, groups of compounds with similar molecular formulae (but differing number of O atoms) generally exhibit distinct trends as a function of NO. For instance, compounds with molecular formulae C$_{10}$H$_{17}$O$_{3,5,7}$ initially increase in abundance with NO as the reaction between NO and HO$_2$ (present in the HO$_2$ source and also generated for every closed-shell carbonyl product formed) yields OH, which promptly react with the excess AP or BP. The abundances of these C$_{10}$H$_{17}$O$_{3,5,7}$ species eventually decrease with additional NO. Based on their composition and behavior as a function of NO, we conclude these are peroxy radicals (RO$_2$), as their reactions with NO dominate in competition with auto-oxidation. In comparison, products of the reactions between NO and RO$_2$ including multi-functional alkyl nitrates (C$_{10}$H$_{17}$NO$_{4,6}$), carbonyls (C$_{10}$H$_{16}$O$_2$s), and acetone continue to increase with NO, and then approach a plateau. The dominant products observed with increasing NO are, as expected, C$_{10}$H$_{16}$O$_2$ (likely pinonaldehyde) for AP and C$_{9}$H$_{14}$O (nopinone) for BP, produced from the reaction between NO and the first generation peroxy radical (C$_{10}$H$_{17}$O$_3$), as shown in Fig. 1. The sensitivity of NH$_4^+$ adduct ionization for most of the 70 identified species is unknown, as such, we show the increase in their ion signals (in units of counts per second, cps) in the presence of HO$_2$.

As illustrated in Fig. 2, three structural isomers of the hydroxy peroxy radical (C$_{10}$H$_{17}$O$_3$) are formed upon the addition of OH to the C=C double bond of AP⁵⁷,⁵⁸ or BP. The three H-abstraction channels together account for 0.12 of the fraction of OH-initiated oxidation of AP⁵⁷,⁵⁸ and 0.099 for BP. For AP, OH-addition to the double bond at the tertiary carbon ($f_4$) followed by breaking of the C-4 ring ($f_5$) is of interest (Fig. 2), given the ability of the resulting RO$_2$ to undergo auto-oxidation.¹¹,¹² For BP, the breaking of the C-4 ring can occur following the OH addition to the primary position.³⁹ The reaction between this ring-opened RO$_2$ isomer of AP and NO produces acetone with reported yields between zero and unity (Table 1). Acetone is also thought to form from two other OH-oxidation pathways of AP + OH: OH addition to the double bond at the more substituted

represent range of values based on experimental and mechanistic uncertainties (see text).

from the ring-opened alkoxy radical, and the hydroxy nitrate yield from NO reaction of that peroxy radical isomer. Values in parentheses represent range of values based on experimental and mechanistic uncertainties (see text).

a comparable increase in unlabeled acetone with no D3-acetone (Fig. 3a). OH oxidation of unlabeled-AP is accompanied by 76.0757), is unchanged relative to when oxidation is turned off (Fig. 3a). OH oxidation of unlabeled-AP is accompanied by a comparable increase in unlabeled acetone with no D3-acetone detected (Fig. 3b). These results are consistent with proposed mechanisms of AP and BP that report acetone is essentially only formed from the three C atoms that comprise the C-4 bridge.

The isotopic labeling together with short (0.7 s) reaction timescales allow us to distinguish acetone formed promptly upon the reaction between NO and the ring-opened RO2 versus those formed from the other two pathways, which require either three (fH-abst) or eight (fB) generations of O2 addition and NO reaction (Fig. 2). The observed acetone produced per AP reacted (Δacetone/ΔAP) as a function of NO is shown in Fig. 3c, alongside that modeled if the H-abstraction pathway (fH-abst) was the only acetone-producing pathway at a yield of 2.1% (γH-abst),16 and if OH-addition to the secondary position (fB) solely produced acetone at a yield of 6% (γB).16 The modeled evolution of Δacetone/ΔAP as a function of NO for neither comes close to simulating the observed Δacetone/ΔAP (Fig. 3c), due to the time required for multiple generations of NO reaction following the initial OH reaction. This result indicates that prompt formation of acetone as observed does not arise from either of these two pathways. In addition, the relative importance of the fB pathway as an acetone source is likely lower than currently reported.

Results from OH-oxidation of isotopically labeled AP that possess three deuterium atoms instead of three hydrogen atoms on one of the two methyl groups attached to the bridge of the C-4 ring (C10H15D3) and that from unlabeled AP (C10H16) are illustrated in Fig. 3a and b. The D3-labeled AP produces D3-labeled acetone, detected as C3H3D3ONH4+ (m/z = 79.0945), while unlabeled acetone, detected as C3H6ONH4+ (m/z = 76.0757), is unchanged relative to when oxidation is turned off (Fig. 3a). OH oxidation of unlabeled-AP is accompanied by a comparable increase in unlabeled acetone with no D3-acetone detected (Fig. 3b). These results are consistent with proposed mechanisms of AP and BP that report acetone is essentially only formed from the three C atoms that comprise the C-4 bridge.

The isotopic labeling together with short (0.7 s) reaction timescales allow us to distinguish acetone formed promptly upon the reaction between NO and the ring-opened RO2 versus those formed from the other two pathways, which require either three (fH-abst) or eight (fB) generations of O2 addition and NO reaction (Fig. 2). The observed acetone produced per AP reacted (Δacetone/ΔAP) as a function of NO is shown in Fig. 3c, alongside that modeled if the H-abstraction pathway (fH-abst) was the only acetone-producing pathway at a yield of 2.1% (γH-abst),16 and if OH-addition to the secondary position (fB) solely produced acetone at a yield of 6% (γB).16 The modeled evolution of Δacetone/ΔAP as a function of NO for neither comes close to simulating the observed Δacetone/ΔAP (Fig. 3c), due to the time required for multiple generations of NO reaction following the initial OH reaction. This result indicates that prompt formation of acetone as observed does not arise from either of these two pathways. In addition, the relative importance of the fB pathway as an acetone source is likely lower than currently reported.

* Xu et al.18 report the quantum calculated branching ratio, or BRring-open (0.32 for AP and 0.44 for BP), which is the fraction of C-4 ring-opened peroxy radical formed following the OH-addition to the secondary position for AP and primary position for BP. We calculate fc using their reported values of BRring-open and the fractions of OH-addition (0.88 for AP and 0.901 for BP) and fractions to OH-addition to the tertiary (0.5 for AP) or primary (0.925 for BP) positions as reported by Vereeken et al.16 and Vereeken and Peeters.39,40 Quantum calculations performed for AP, assumed to be identical for this work for BP.
Observations in Fig. 3c follow the trends expected if acetone is a product predominantly of the reaction between the ring-opened RO$_2$ isomer ($f_c$) and NO, which is in competition with a fast unimolecular reaction, as shown in eqn (1)-(3). In eqn (1), the acetone formation rate is defined by the reaction between NO and the ring-opened RO$_2$ isomer where $\alpha_c$ is the corresponding alkyl nitrate yield, and $\beta_c$ is the branching ratio of the resulting RO that undergo C-C scission to yield acetone (Fig. 2). Chemical loss of acetone by OH oxidation is negligible given the 0.7 s reaction time and because the AP or BP is in excess.

$$\frac{d[\text{acetone}]}{dt} = (1 - \alpha_c)\beta_c k_{RO2+NO}[NO][RO2]$$

Eqn (2) shows the mass balance for the ring-opened RO$_2$ isomer, produced at a fraction, $f_{C}$, per reaction of OH with MT, and lost to bimolecular and unimolecular reactions, such as reaction with NO and auto-oxidation, respectively. Reactions with RO$_2$ and HO$_2$ become negligible with the addition of NO.

$$\frac{d[RO2]}{dt} = f_C k_{MT+OH}[OH][MT] - k_{RO2+NO}[NO][RO2] - k_{auto}[RO2]$$

Thus, $\Delta$acetone/$\Delta$AP increases with NO and then plateaus as shown in eqn (3).

$$\frac{\Delta\text{acetone}}{\Delta\text{MT}} = \frac{(1 - \alpha_c)f_c \beta_c k_{RO2+NO}[NO]}{k_{auto} + k_{RO2+NO}[NO]}$$

Assuming negligible acetone contributions from the $f_b$ and $f_{H-abs}$ pathways, the absolute value that $\Delta$acetone/$\Delta$MT approaches at high NO constrains the yield, $\gamma_C$ ($=f_C \times \beta_C$), of acetone produced per OH-oxidation of MT, for a given value of $\alpha_C$, for which we assume 0.15. The modeled variability in $\Delta$acetone/$\Delta$MT (Fig. S3†) given the variability in reported $\alpha_C$ values (Table 1) is within the uncertainties of $\gamma_C$ derived from the non-linear least squares fit, shown shaded in Fig. 3c. The alkyl nitrate yields of all other RO$_2$ — which can affect the production of closed-shell carbonyls, and hence, HO$_2$, which promptly react with NO to form OH that then reacts with the excess AP or BP — likewise do not significantly affect $\Delta$acetone/$\Delta$MT (Fig. S4†).

Assuming unity for $\beta_C$, as currently reported in the MCM, the calculated $f_C$ would be defined by $\gamma_C$, which are 0.059 (0.05, 0.07) and 0.083 (0.08, 0.09) for AP and BP, respectively (Fig. 3c and d). To provide an independent estimate of $f_C$, we conducted quantum calculations to assess the relative importance of the five possible fates of the alkyl radical (RO) stemming from the C-4 ring-opened isomer of AP, including the C-C bond scission path to yield acetone. These calculations show that the acetone-producing bond scission branching, $\chi_C$, is either 0.07 (OH up) or 0.18 (OH down), depending on the diastereomer formed. The formation of an endocyclic ether and an intra-molecular H-shift dominate the RO fate (Fig. S5†). As our technique is unable to distinguish structure (OH up or down), we use the mean of the two calculated alkoxyl radical branching ratio, $\beta_C$ (=0.125). As such, our results indicate $f_C$ of the C-4 ring-opening isomers are 0.47 (0.2, 0.6) for AP, and 0.66 (0.4, 0.8) [assuming identical $\beta_C$ for BP], where the uncertainty range indicated in the parentheses is due mainly to the fate of the alkyl radical, not experimental variance which is of order 0.08. Contribution of acetone from H-abstraction pathway ($f_{H-abs}$) and/or the OH-addition to the secondary position pathway ($f_b$) would lower our calculated $f_C$ values. Though Xu et al. calculated C-4 ring opening branching ratio of 0.32 for the tertiary alkyl radical resulting from OH-addition to to AP, that ratio is 0.97 if determined from our observations of the three hydroxynitrate isomers (C$_{10}$H$_{17}$NO$_3$). Our determination of $f_C$ of 0.47 and an OH-abstraction fraction of 0.12, imply OH-addition to form the secondary alkyl radical is at most 0.40.

In addition to allowing the resolution of different RO$_2$ formation pathways, our short reaction time study constrains the unimolecular auto-oxidation rate ($k_{auto}$), which is defined by the slope of $\Delta$acetone/$\Delta$MT as a function of NO, per eqn (3). We perform a non-linear least-squares fit utilizing eqn (3) on the observed $\Delta$acetone/$\Delta$MT versus NO to determine $k_{auto}$ and its uncertainty. We find $k_{auto}$ for the first generation C-4 ring-opened C$_{10}$H$_{17}$O$_3$ peroxy radicals of AP and BP are 2.9 (1.1, 4.7) s$^{-1}$ and 0.8 (0.4, 1.6) s$^{-1}$, respectively where the uncertainty range in parentheses stems from least squares fit parameters. These determinations are independent of the calculations of $f_C$ and $\beta_C$. The auto-oxidation rate for AP is comparable to those previously published. That BP is on the lower end, though there is greater variance in published values for BP (Table 2).

One possible reason for the discrepancy is that experimental studies such as ours and that of Xu et al. cannot distinguish diastereomers, which is relevant for AP. The ring-opened hydroxy peroxy radical of BP is not affected by stereoelectivity as the hydroxyl functional group is not attached to the 6-member ring. Even amongst computational studies, however, there is not perfect agreement on the rates and, at times, the relative importance of the different pathways. Such difficulties highlight the challenging nature of elucidating chemical mechanisms. For instance, a few computational studies have determined that the C-4 ring opened hydroxy peroxy radicals preferentially form a 6-member endocyclic peroxy (endo-6, see Table 2), in particular, for BP. The resulting C$_{10}$H$_{17}$O$_3$ peroxy radical now with two O atoms within the newly-formed 6-member ring is, however, slow to undergo additional auto-oxidation given that it is ring-constrained.

To determine whether the first generation C$_{10}$H$_{17}$O$_3$ radicals undergo allylic or endocyclic auto-oxidation, we constrain $k_{auto}$ for the subsequent second generation peroxy radicals (C$_{10}$H$_{17}$O$_3$) by comparing the modeled and observed evolution of C$_{10}$H$_{17}$O$_3$ as a function of NO. In particular, we use the inflection point in NO at which the RO$_2$ abundance starts to decrease, testing its rate of auto-oxidation versus reaction with NO. As shown in Fig. 4, $k_{auto}$ for the AP-derived C$_{10}$H$_{17}$O$_3$ exceeds 20 s$^{-1}$, as increasing the modeled rate above 20 s$^{-1}$ does not result in significant improvement in model-observation agreement. For the BP-derived C$_{10}$H$_{17}$O$_3$, $k_{auto}$ is 11.1 (6.2, 16) s$^{-1}$. That the $k_{auto}$ of C$_{10}$H$_{17}$O$_3$ are much greater than those of
Table 2  Auto-oxidation rates for the first generation C-4 ring-opened hydroxy peroxy (C_{10}H_{17}O_{7}) radical for α and β-pinene. For values derived from theoretical calculations, we also present, when available, the diastereomer-specific auto-oxidation rates of the individual pathways. "1.5" and "1.6" denote allylic H-shifts, whereas "endo-6" denotes formation of an endocyclic peroxy product. Values from this study and those of Xu et al.\textsuperscript{18} represent the overall rates as neither experimental works are able to distinguish the syn versus anti diastereomers. Values in parentheses represent upper and lower bounds due to experimental and/or fitting errors.

\textsuperscript{a} Stereoselectivity does not apply to the C-4 ring-opened hydroxy peroxy radical of BP given that the hydroxyl (-OH) functional group is not on the 6-member ring, whereas those of AP can exist as anti (-OH on the 6-member ring relative to the t-butyl peroxy group) and syn.

Fig. 4 Normalized traces of the second generation C_{10}H_{17}O_{5} peroxy radicals observed during the OH-oxidation of (a) AP and (b) BP, as a function of NO. Conducting numerous simulations to optimize model-observation agreements allowed us to define an optimal range of kauto \textsubscript{endo} for each, which for AP exceeds 20 s\textsuperscript{−1} and 11.1 (6.2, 16) s\textsuperscript{−1} for BP. Three simulated traces of C_{10}H_{17}O_{5} with widely varying rates of their auto-oxidation are shown.

C_{10}H_{17}O_{3} suggests that the first generation C_{10}H_{17}O_{3} peroxy radicals preferentially undergo allylic and not endocyclic auto-oxidation. These observations are consistent with the mechanisms proposed by Berndt et al.\textsuperscript{13} which report theoretical calculations that C_{10}H_{17}O_{3} (more so than C_{10}H_{17}O_{2}) undergo rapid H-shifts to form the endo-cyclic peroxy radicals (C_{10}H_{17}O_{2}), which are much slower to undergo an additional H-shift given the endo-peroxide ring. Our observational estimates of kauto for the third generation peroxy radicals (C_{10}H_{17}O_{2}), however, are limited by the fact that their abundances approach instrument detection limits at moderate to high NO levels.

Lastly, recent studies offer contrasting reports on the importance of the H-abstraction pathway. Berndt,\textsuperscript{43} using a fast flow tube coupled to an ethylaminium ionization mass spectrometer observed negligible products of H-abstraction by OH from α-pinene, whereas Shen et al.\textsuperscript{44} using an atmospheric simulation chamber coupled to a nitrate ionization mass spectrometer found that the dominant fraction of the products, namely HOMs, from OH oxidation of α-pinene is from H-abstraction, not OH-addition. At low NO, we observed an H-abstraction product (C_{10}H_{17}O_{4}) only for AP, but not BP (Fig. S6\textsuperscript{†}). The amount of C_{10}H_{17}O_{4}, assuming comparable sensitivities to the C_{10}H_{17}O_{3} RO_{2}, suggest H-abstraction yield of ∼3%, similar to the theoretical work (9%) of Vereecken et al.\textsuperscript{16} Moreover, at low NO, the C_{10}H_{17}O_{3} RO_{2} are dominated by those possessing 3, 5, and 7 oxygen atoms (Fig. S6\textsuperscript{†}), consistent with the observations of Berndt.\textsuperscript{43} A more detailed analysis of the H-abstraction pathway is beyond the scope of this paper.

4 Conclusions

We present a novel transverse atmospheric pressure ammionium adduct ionization mass spectrometer coupled to a fast flow tube to directly observe OH-initiated oxidation products of AP and BP, including peroxy radicals and those formed from their reaction with NO. By systematically adding NO to probe the fate of these peroxy radicals in competition with auto-oxidation over short timescales (∼0.7 s), with and without isotopically labeled precursors, we distinguish prompt acetone formation from the C-4 ring-opening pathway versus those that require multiple generations of NO reactions. Using quantum calculations to constrain the branching ratio of acetone formed from the ring-opened alkoxy radical (0.125), we find that the fractions of OH-oxidation of AP and BP that form the ring-opened peroxy radicals are 0.47 (0.2, 0.6) and 0.66 (0.4, 0.8),
respectively. We also determine a narrow range for the auto-oxidation rates of these first-generation ring-opened peroxy radicals as well as of their associated auto-oxidation products, thereby providing a more complete description of HOM production channels from OH oxidation of AP and BP.
